Recently, diagnoses of small renal masses and renal cell carcinoma (RCC) have increased due to the widespread use of radiographic imaging studies (computerized tomography, magnetic resonance imaging). It appears that biological factors such as obesity and tobacco use increase the risk for RCC. In general, small malignant renal masses are low stage and low grade. The management of asymptomatic renal masses is a surgical challenge since overtreatment of benign masses is not desired, especially for patients with complex medical comorbidities, elderly patients, and those with impaired renal function.

Partial nephrectomy has been considered the gold standard when treating small renal masses. However, technical challenges and possible irreversible ischemia-reperfusion injury should be considered when treating these lesions. Preservation of renal function without compromising oncological control is the foundation for nephron-sparing surgery. Laparoscopic renal cryoablation (LRC) emerges as an option to treat small renal masses due to the less invasive procedure with low intraoperative complications rates, with no renal ischemia-reperfusion injury and comparable medium term follow up. It is our objective to demonstrate our technique to perform an effective small renal tumor cryoa blation using the laparoscopic approach.

Key Words: renal cancer, renal cryoablation, laparoscopic cryoa blation

Introduction

The diagnoses of small renal masses and renal cell carcinoma (RCC) have increased due to the widespread use of radiographic imaging studies.1 Partial nephrectomy has been considered the gold standard when treating small renal masses.2,3 However, technical challenges can lead to irreversible ischemia-reperfusion renal injury during the treatment of these lesions.2,3 Currently, the evolution of technology allowed surgeons to treat the small renal lesions with thermo ablative techniques i.e.; cryoa blation. Uchida et al described the use of liquid nitrogen to treat renal tumors with cryotherapy, resulting in low complication rates.4

Currently, the evolution of cryotechnology has allowed for the use of argon and helium gas for
cryoablation and thawing respectively, with effective therapy of renal cancer cells even when performed by laparoendoscopic single-site surgery (LESS). The cryoablative site is categorized by two zones: a central zone characterized by coagulative necrosis, and a peripheral zone characterized by varying degrees of cellular death and injury. The mechanisms of cellular destruction and damage include both direct, immediate physical damage to cells, and more delayed cell death due to local hypoxia and apoptosis.

The development of intraoperative ultrasound enabled real-time monitoring of tissue freezing. When ultrasound technology is used with new cryotherapy technology including the use of argon gas to freeze and helium gas to actively thaw, outcomes improved significantly for this less invasive technique.

Surgical technique

Preoperative care
Patients are informed to fast after midnight the day prior to the procedure. No bowel preparation is needed unless the patient previously had any extensive abdominal surgery.

Anesthesia and patients position
General anesthesia with muscle paralytics and endotracheal intubation are required. The patient is placed in a modified flank position at a 30-degree angle. The lower leg is flexed while the upper leg is extended. All pressure points are padded and the patient is secured to the table with 3 inch cloth tape, Figure 1. Special attention is required to prevent injury to the fibular, radial, brachial, and axillary nerves and plexus. The cloth tape is applied to the pelvis, shoulder, and legs above the knees to ensure the patient’s safety.

Pneumoperitoneum and trocars placement
Pneumoperitoneum is accomplished by placing a Verres needle in the umbilicus for patients who haven’t had previous abdominal surgery; or in the upper quadrant (left or right) with a CO₂ insufflation pressure of 15 mHg-20 mmHg. For all anterior tumors, a LESS technique is performed through a single, peri-umbilical incision of 2.5 cm, Figure 2. For other tumor locations, the placement requires the following:

a) one 5 mm trocar is placed at the sub-xiphoid site;
b) one 10 mm trocar at the umbilicus for a deflectable Endo-Eye camera (Olympus America Inc., Southborough, MA, USA);
c) another 12mm trocar at the mid-clavicular line as the entry point.

Renal dissection
After insertion of the camera, a review of the operative field is performed to inspect and detect unintentional injuries during trocar placement.

Visceral rotation of the colon is performed and only the tumor region should be carefully dissected. The kidney is exposed with minimal dissection after intraoperative ultrasonography is performed through the 12 mm trocar. The Gerota’s fascia is opened at the lesion site to expose the tumor. Perinephric fat surrounding the tumor is sent for pathology.

Cryoprobes placement
An initial 1.7 mm cryoprobe is inserted into the mass transabdominally through a skin puncture and placed into the lesion. The probe is anchored by freezing the tumor 1 mm-2 mm from the probe. Triangulation of

How I do it: laparoscopic renal cryoablation (LRC)

Discussion

A systematic review of the literature identified that laparoscopic renal cryoablation (LRC) has acceptable midterm (3-5 years) oncological outcomes with low recurrence rate. LRC has proven to be a safe procedure with a low overall complication rate. It can even be performed on elderly patients affected by comorbidity that are typically categorized as high surgical risk.³

Another systematic review and meta-analysis reported that laparoscopic renal cryoablation was associated with significantly shorter operative times, lower estimated blood loss, shorter length of stay, and decreased risk of perioperative complications when compared to laparoscopic and robotic partial nephrectomy. However, LRC is also associated with an increased risk for local recurrence and tumor progression.³ Balancing cancer management with the risk of perioperative complications is crucial for patient counseling and selecting the appropriate procedure. Currently, there are no prospective randomized controlled studies with long term follow up. Local recurrence after cryoablation can be well evaluated with contemporary tomographic studies and contrast enhancement.

Renal function after LRC has not shown impairment in our midterm follow up.⁸ Patients with solitary kidney that present renal tumors or patients with multiple tumors can benefit from a less invasive procedure that preserves renal function and increases the chance of having satisfactory functional outcomes, especially patients with the von Hippel-Lindau syndrome.⁸

The American Urological Association (AUA) recommends nephron sparing surgery (partial nephrectomy) as the standard of care for T1a renal tumors.³ Cryosurgery is considered first-line therapy that can be recommended to elderly patients, patients with multiple comorbidities, and patients with a solitary kidney.³ The definite oncological efficacy and renal function preservation will be delineated by future long term follow up studies. Moreover, recurrences after cryoablation may be related to the technique rather than the technology as demonstrated by studies treating other diseases i.e.; localized prostate cancer.⁹,¹⁰

Conclusion

LRC is established as a less invasive and simpler surgical technique that is a great option for primary treatment of small renal neoplasms. It is associated with low complication rates and has very low impact on renal function. Patients with complex medical comorbidities, elderly patients, and those with impaired renal function appear to benefit from this technique for the treatment of small renal masses. □
